Abstract

Let X be a closed manifold with $(X) = 0$, and let $f\colon X \,!\; S^1$ be a circle-valued Morse function. We de ne an invariant I which counts closed orbits of the gradient of f, together with flow lines between the critical points. We show that our invariant equals a form of topological Reidemeister torsion de ned by Turaev [28].

We proved a similar result in our previous paper [7], but the present paper re nes this by separating closed orbits and flow lines according to their homology classes. (Previously we only considered their intersection numbers with a xed level set.) The proof here is independent of the proof in [7], and also simpler.

Aside from its Morse-theoretic interest, this work is motivated by the fact that when X is three-dimensional and $b_1(X) > 0$, the invariant I equals a counting invariant $I_3(X)$ which was conjectured in [7] to equal the Seiberg{Witten invariant of X. Our result, together with this conjecture, implies that the Seiberg{Witten invariant equals the Turaev torsion. This was conjectured by Turaev [28] and re nes the theorem of Meng and Taubes [14].

1   Introduction

Given a flow on a manifold, it is natural to ask how many closed orbits there are. It turns out that for some well-behaved flows, the numbers of closed orbits in di erent homology classes are related to the Reidemeister torsion of the underlying manifold. For example, Fried [2] de ned a \twisted Lefschetz zeta function" counting closed orbits of certain nonsingular hyperbolic flows and showed that it equals a version of topological Reidemeister torsion, which is independent of the flow.

In this paper, we are interested in the gradient flow of a circle-valued Morse function. For singular flows such as this one, the zeta function is no longer invariant under deformation of the flow. It turns out that this lack of invariance can be xed by considering the Novikov complex, which counts gradient flow lines between critical points. We will show that one can obtain a topological invariant by multiplying the zeta function by the Reidemeister torsion of the Novikov complex. We call the resulting invariant I.

In our previous work [7], we de ned a weaker version of I and showed that it equals a form of topological Reidemeister torsion. Later we received a preprint from Turaev [28] de ning a re ned version of the latter invariant, which we call \Turaev torsion" here. Along similar lines we can re ne the Morse theoretic invariant in [7] to obtain the invariant I. The main result of this paper asserts that I equals Turaev torsion.

Our previous methods are not quite su cient to prove this re nement, so here we introduce a di erent and simpler approach. This paper is independent of [7], except that the latter paper de nes certain compacti cations in Morse theory which we use here, and also provides more background and context.

We now proceed to de ne our invariant I more precisely and state our main theorem. We then describe the application to three-dimensional Seiberg{Witten theory. In section 2 we give some background de nitions, and in section 3 we prove the main theorem. In section 4 we give more details on the relation to Seiberg{Witten theory.

1.1   Statement of results

The basic setup for this paper is as follows. Let X be a closed connected oriented n-dimensional manifold. We assume throughout that $(X) = 0$, so that we can de ne Reidemeister torsion. Also, our result is most interesting when $b_1(X) > 0$.

Let $f: X \to S^1$. In order to consider the gradient flow of f, we endow X with a Riemannian metric. We make the following assumptions:

Assumption 1.1 (a) f is a Morse function.

  (b) The ascending and descending manifolds of the critical points of f intersect transversely (see section 2.1).

  (c) The closed orbits of the gradient ∇f are nondegenerate (see below).

A standard transversality argument shows that these assumptions hold if f and the metric are generic.

A *closed orbit* is a nonconstant map $\gamma : S^1 \to X$ with $\gamma'(t) = -\nabla f$ for some $\lambda > 0$. We declare two closed orbits to be equivalent if they differ by reparametrization. The *period* $p(\gamma)$ is the largest integer p such that γ factors through a p–fold covering $S^1 \to S^1$. A closed orbit is *nondegenerate* if $\det(1 - d\phi(x)) \ne 0$, where ϕ is the pth return map at a point $x \in \gamma(S^1) \subset X$. If so, the *Lefschetz sign* $\epsilon(\gamma)$ is the sign of this determinant.

Notation 1.2 Let $H_1 := H_1(X)$. Let $\alpha \in H^1(X;\mathbb{Z})$ denote the pullback by f of the "upward" generator of $H^1(S^1;\mathbb{Z})$.

Let $\Lambda = \mathrm{Nov}(H_1; -\alpha)$ denote the *Novikov ring* [17, 5], consisting of functions $H_1 \to \mathbb{Z}$ that are finitely supported on the set $\{h \in H_1 \mid -\alpha(h) \le C\}$ for each $C \in \mathbb{R}$. This ring has the obvious addition, and the convolution product. We denote a function $a: H_1 \to \mathbb{Z}$ by the (possibly infinite) formal sum $\sum_{h \in H_1} a(h) \cdot h$.

Definition 1.3 [2, 20] We count closed orbits with the *zeta function*, which is a function $H_1 \to \mathbb{Z}$ defined, in the above notation, by

$$\zeta := \exp\left(\sum_{\gamma \in O} \frac{\epsilon(\gamma)}{p(\gamma)}[\gamma]\right) . \tag{1}$$

Here O denotes the set of closed orbits, and $[\gamma] := \gamma_*[S^1]$ is the homology class of γ in $H_1(X)$.

A compactness argument using Assumption 1.1, together with the observation that $-\alpha([\gamma]) > 0$ for all γ, shows that $\zeta \in \Lambda \otimes \mathbb{Q}$.

We remark that there is also a product formula [3, 7, 8]

$$\zeta = \prod_{\gamma \in I} (1 - (-1)^{i_\gamma-}[\gamma])^{-(-1)^{i_0}} . \tag{2}$$

Here I denotes the set of irreducible (period 1) closed orbits, and $i_-(\ )$ and $i_0(\ )$ denote the numbers of real eigenvalues of the return map in the intervals $(-1\,;-1)$ and $(-1\,;1)$, respectively. Equation (2) shows that in fact $\ 2\ $, ie, $\ $ has integer coe cients. A third formula for the zeta function, in terms of xed points of return maps, is given in equation (13).

We now introduce a notion of topological Reidemeister torsion following Turaev [28], and an analogous notion of Morse-theoretic torsion. Detailed de nitions are given in section 2.3.

Let $\tilde{X}$ denote the universal (connected) abelian cover of X, whose automorphism group is $H_1(X)$. A smooth triangulation of X lifts to $\tilde{X}$ and gives rise to a chain complex $C_\ast(\tilde{X})$ over $\mathbb{Z}[H_1]$. The Reidemeister torsion of this complex is an element of $Q(\mathbb{Z}[H_1])= \ H_1$, where $Q(R)$ denotes the total quotient ring of R. The $\ H_1$ ambiguity arises because the Reidemeister torsion depends on a choice of ordered basis.

Turaev [27] showed that the H_1 ambiguity can be resolved by the choice of an \Euler structure". The space $\mathrm{Eul}(X)$ of Euler structures is a natural a ne space over $H_1(X)$, reviewed in section 2.2. One can also resolve the sign ambiguity by choosing a *homology orientation* of X, ie, an orientation o of $\bigoplus_i H_i(X;\mathbb{Q})$ (see [26]). We can then de ne the *Turaev torsion*

$$(X;o)\colon\ \mathrm{Eul}(X)\ !\ Q(\mathbb{Z}[H_1])\,: \qquad (3)$$

This is an H_1\{equivariant map which does not depend on the triangulation. We write $(X):= (X;o)$; this is an H_1\{equivariant map $\mathrm{Eul}(X)\ !\ Q(\mathbb{Z}[H_1])= \ 1$.

Example 1.4 If X is the 3\{manifold obtained by zero surgery on a knot $K\ S^3$, then for a suitable Euler structure $\ $,

$$(X)(\ ) = \frac{\mathrm{Alex}(K)}{(1-t)^2}$$

where $\mathrm{Alex}(K)\ 2\ \mathbb{Z}[t\,;t^{-1}]= \ 1$ is the Alexander polynomial of K and t is a generator of $H_1(X)\ '\ \mathbb{Z}$.

On the Morse theory side, the Novikov complex $CN_\ast$ is a chain complex over the Novikov ring $\ $, whose chains are generated by critical points of the pullback of f to $\tilde{X}$, and whose boundary operator counts gradient flow lines between critical points (see section 2.1). We can similarly de ne the *Morse-theoretic torsion*

$$(CN_\ast)\colon\ \mathrm{Eul}(X)\ !\ Q(\ )= \ 1\,: \qquad (4)$$

Definition 1.5 Define $I: \mathrm{Eul}(X) \to Q(\Lambda)^{\times}=\Lambda$ to be the product of the zeta function and the Morse-theoretic torsion:

$$I := \zeta \tau(CN_*).$$

Theorem 1.6 *The Morse theory invariant I is independent of the metric and depends only on the homotopy class of f, ie the cohomology class α.*

One can prove this *a priori*; see [7] for the rough idea and [6] for the details. Although this may help define related invariants in other contexts, in the present context it is easier to compute I directly, which will prove Theorem 1.6 *a posteriori*. That is what we will do in this paper.

Theorem 1.7 (Main theorem) *Our Morse theory invariant I is equal to the topological torsion:*

$$I = i(\tau(X))$$

as maps $\mathrm{Eul}(X) \to Q(\Lambda)^{\times}=\Lambda$.

Here $i: Q(\mathbb{Z}[H_1]) \to Q(\Lambda)$ is induced by the inclusion $\mathbb{Z}[H_1] \to \Lambda$.

Remarks 1.8 (1) In the extreme case when there are no critical points, X is a mapping torus and this theorem reduces to an equivariant version of the Lefschetz fixed point theorem, cf [15, 3].

(2) The extreme case when $\alpha = 0$, so that f lifts to a real-valued Morse function, is also essentially classical (cf [16]), and we treat it in section 2.4. In this case the Morse-theoretic torsion is a topological invariant; lack of invariance and existence of closed orbits arise simultaneously when we pass from real-valued to circle-valued Morse theory.

(3) The class $\alpha \in H^1(X)$, regarded as a map $H_1(X) \to \mathbb{Z}$, induces a map $\Lambda \to \mathbb{Z}((t))$ sending $h \mapsto t^{\alpha(h)}$. This in turn induces a partially defined map $Q(\Lambda) \to \mathbb{Q}((t))$. One can deduce the main result of our previous paper [7] by applying this map to Theorem 1.7.

(4) The statement of Theorem 1.7 makes sense when df is replaced by a generic closed 1–form ω and the Novikov ring is graded by $-[\omega]$. It seems possible to extend Theorem 1.7 to this case by approximating ω by closed 1–forms in rational cohomology classes, to which Theorem 1.7 applies. Another proof for closed 1–forms is given in [6] by first proving Theorem 1.6 for closed 1–forms, and then using this to reduce to the real-valued case.

(5) Some previous papers, such as [19], studied the torsion of the Novikov complex (or the Whitehead torsion, which is sharper but only de ned \relatively" unless the Novikov complex is acyclic), without considering the zeta function. In this case one can still obtain a topological invariant by modding out by units in the Novikov ring with leading coe cient 1. This is useful for understanding the obstructions to the existence of nonvanishing closed 1{forms [10, 4]. However, the extra information in the zeta function is important for the connection with Seiberg{Witten theory below.

(6) A homology orientation of X can apparently remove the sign ambiguity in (CN). However we have not checked if Theorem 1.7 holds with the sign ambiguity removed this way.

1.2   Application to Seiberg{Witten theory

We now consider the special case when $\dim(X) = 3$ and $b_1(X) > 0$. Let $\mathrm{Spin}^c(X)$ denote the set of spin-c structures on X. Given a homology orientation o, the Seiberg{Witten invariant of X is a function

$$\mathrm{SW}_{X;o}\colon \mathrm{Spin}^c(X) ! \ \mathbb{Z}$$

which counts $\mathbb{R}${invariant solutions to the Seiberg{Witten equations on $X \quad \mathbb{R}$, modulo gauge equivalence. (See eg [13, 14, 18].)

Taubes [24] has shown that the SW invariant of a symplectic four{manifold equals a \Gromov invariant" counting pseudoholomorphic curves. In [7] we proposed that using similar analysis, one might be able to show that the SW invariant of a 3{manifold is equal to a Morse theory invariant

$$I_3\colon \mathrm{Spin}^c(X) ! \ \mathbb{Z}:$$

The invariant I_3 counts certain unions of closed orbits and flow lines of the gradient vector eld of a Morse function $f\colon X ! \ S^1$ with no index 0 or 3 critical points. We review the de nition of I_3 in section 4.

Conjecture 1.9 [7] The Seiberg{Witten invariant agrees with our Morse theory invariant:

$$\mathrm{SW}_{X;o} = \ I_3:$$

(When $b_1(X) = 1$, the SW invariant also depends on a choice of \chamber", and in this conjecture we use the chamber determined by $r \ df$ for $r >> 0$.)

Remark 1.10 If f has no critical points, and if we arrange for df to be harmonic, then this conjecture is a corollary of Taubes' theorem [24] applied to the symplectic four–manifold $(X \times S^1, df \wedge ds + \ast_X df)$. Here s denotes the S^1 coordinate. The idea is that for a suitable homology orientation, if $\mathfrak{s} \in \mathrm{Spin}^c(X)$, then

$$\mathrm{SW}_{X;o}(\mathfrak{s}) = \mathrm{SW}_{X \times S^1}(\ast \mathfrak{s}) = \mathrm{Gr}_{X \times S^1}(\ast \mathfrak{s}) = I_3(\mathfrak{s}).$$

The rst equality expresses the fact that all solutions to the SW equations on $X \times S^1$ are S^1–invariant; see [18] for details of this equality. The second equality is Taubes' theorem; here $\mathrm{Gr}_{X \times S^1}(\ast \mathfrak{s})$ counts, in the sense of [25], pseudoholomorphic curves in a certain S^1–invariant homology class in $X \times S^1$. An energy argument shows that for a suitable almost complex structure, every such curve is a union of closed orbits of ∇f crossed with S^1. This leads to the third equality (cf [8, Thm. 0.1]), using the fact that I_3 is a reparametrization of the zeta function in this case.

Salamon has proved a statement equivalent to Conjecture 1.9 in this case using a di erent method [22].

In another direction, Turaev [28] conjectured a combinatorial formula for the Seiberg–Witten invariant as follows. If $\dim(X) = 3$ and $b_1(X) > 1$, then for an Euler structure $\ast$, the torsion $\tau(X; o)(\ast)$ is actually in the group ring $\mathbb{Z}[H_1]$. If $b_1 = 1$, then $i(\tau(X; o)(\ast)) \in \ast$, rather than in the quotient ring. Given a homology orientation o, one can then de ne a map

$$T(X; o): \ \mathrm{Eul}(X) \longrightarrow \mathbb{Z},$$
$$\ast \longmapsto i(\tau(X; o)(\ast))(0).$$

where (0) indicates evaluation on $0 \in H_1$. (This depends on the sign of $[df]$ when $b_1 = 1$.) There is also a natural isomorphism $\iota: \mathrm{Spin}^c(X) \to \mathrm{Eul}(X)$ ([27], see section 4.3).

Conjecture 1.11 (Turaev [28]) The Seiberg–Witten invariant agrees with the Turaev torsion:

$$\mathrm{SW}_{X;o} = T(X; o) \circ \iota: \ \mathrm{Spin}^c(X) \to \mathbb{Z}.$$

This statement is a re nement of the theorem of Meng and Taubes [14], which gives an "averaged" version of this equivalence, in which one sums over spin-c structures that di er by torsion elements of $H^2(X; \mathbb{Z})$.

The invariant I_3 turns out to be a reparametrization of the more general invariant I. Thus we can apply Theorem 1.7 to prove:

Theorem 1.12 *Conjecture 1.9 is equivalent to Conjecture 1.11 (modulo signs).*

The detailed proof is given in section 4.

Update (1) Three days after the rst version of this paper was posted on the internet, a preprint by Pajitnov [20] appeared, giving a result similar to Theorem 1.7, using Whitehead torsion.

(2) Turaev [29] has shown how to re ne the methods of Meng and Taubes to prove Conjecture 1.11, modulo signs. Together with our results, this indirectly proves Conjecture 1.9. However, one might still desire a direct analytic proof. The following is a summary of the situation:

$$
\begin{array}{ccc}
 & \text{Thm. 1.7} & \\
S^1 \text{ Morse theory} & = & \text{Turaev torsion} \\
\text{analytic proof?} \ \ggg & & \text{Meng-Taubes/Turaev} \\
 & \text{Seiberg{Witten} &
\end{array}
$$

Acknowledgments This paper would not exist were it not for Taubes' work on Seiberg{Witten and Gromov invariants. We thank him for sharing his ideas generously. We also thank R Bott, R Forman, and D Salamon for helpful conversations.

2   Background

We now give some necessary background. Section 2.1 reviews the de nition of the Novikov complex, which counts gradient flow lines between critical points. Section 2.2 reviews Turaev's Euler structures, which are needed for the most re ned version of Reidemeister torsion. Section 2.3 gives the precise de nitions of the versions of Reidemeister torsion that we use. Finally, section 2.4 proves Theorem 1.7 for real-valued Morse functions, as a warmup for some of the arguments in section 3.

2.1   The Novikov complex

We begin with some standard de nitions from Morse theory. If p is a critical point in X of f or in $\tilde{X}$ of the pullback of f, the *descending manifold* $D(p)$ is the set of all points x such that upward gradient flow starting at x converges

to p. Similarly the *ascending manifold* $A(p)$ is the set of all points from which downward gradient flow converges to p. If $\text{ind}(p) = i$, then $D(p)$ and $A(p)$ are embedded open balls of dimensions i and $n - i$ respectively.

The *Novikov complex* (CN_*, ∂^f) is defined as follows. On $\tilde{X}$, we can lift our Morse function to a map $\tilde{f}: \tilde{X} \to \mathbb{R}$. Let CN_i denote the set of (possibly infinite) linear combinations of critical points of index i in $\tilde{X}$, such that for each $C \in \mathbb{R}$, the sum contains only finitely many critical points $p \in \tilde{X}$ with $\tilde{f}(p) > C$. The action of H_1 on the critical points by covering transformations induces an action of the Novikov ring on CN_i. In fact CN_i is a free module; one can specify a basis for CN_* by choosing a lift of each critical point in X to $\tilde{X}$.

We define $\partial^f: CN_i \to CN_{i-1}$ as follows. If $p, q \in \tilde{X}$ are critical points of index i and $i - 1$ respectively, let $\langle \partial^f p, q \rangle$ denote the signed number of gradient flow lines from p to q. If p is a critical point of index i, define

$$\partial^f p := \sum_q \langle \partial^f p, q \rangle q$$

where the sum is over all critical points $q \in \tilde{X}$ of index $i - 1$. We count flow lines using the sign conventions from [7]. These conventions are chosen so that $(\partial^f)^2 = 0$ and so that equation (16) holds.

Theorem 2.1 (Novikov) *The homology of the Novikov complex is naturally isomorphic to the homology of the \half-infinite" chains in $\tilde{X}$:*

$$H_*(CN_*, \partial^f) \simeq H_*(C_*(\tilde{X})_\ast).$$

See eg [17, 19, 21, 7]. For example, if $X = S^1$ and $f: S^1 \to S^1$ has nonzero degree, then the homology of the Novikov complex vanishes.

2.2 Euler structures

We now discuss three different notions of \Euler structure" and how they relate. One can ignore this material at the expense of allowing an H_1 ambiguity in Reidemeister torsion.

Definition 2.2 (Turaev [27]) If X is a closed smooth manifold with $\chi(X) = 0$ and $n = \dim(X) > 1$, a *smooth Euler structure* on X is a nonsingular vector field on X, where two such vector fields are declared equivalent if their restrictions to the complement of a ball in X are homotopic through nonsingular vector fields. We let $\text{Eul}(X)$ denote the space of smooth Euler structures.

By obstruction theory, $\mathrm{Eul}(X)$ is an affine space over $H^{n-1}(X; \pi_{n-1}(S^{n-1})) = H_1(X)$. (It is nonempty since $\chi(X) = 0$.)

The following alternate definition of smooth Euler structures is useful for Morse theory, and also works well when $n = 1$. If v is a vector field on X with nondegenerate zeroes, let $H_1(X; v)$ denote the set of homology classes of 1–chains $\gamma \subset X$ with $\partial\gamma = v^{-1}(0)$, where the points in $v^{-1}(0)$ are oriented in the standard way. The set $H_1(X; v)$ is a subset of the relative homology $H_1(X; v^{-1}(0))$ and is an affine space over $H_1(X)$.

Definition 2.3 One can show by a cobordism argument that the spaces $H_1(X; v)$ for different v's are canonically isomorphic to each other, and hence to a single space. We call this space $\mathrm{Eul}(X)$. We let $i_v: H_1(X; v) \to \mathrm{Eul}(X)$ denote the canonical isomorphism.

If $n > 1$, we can go from Definition 2.3 to Definition 2.2 as follows. Given $\gamma \in H_1(X; v)$, we can represent γ by disjoint paths connecting the zeroes of v in pairs. We then construct a nonsingular vector field by cancelling the zeroes of v in a neighborhood of γ. (If v has no zeroes, we send $0 \in H_1(X) = H_1(X; v)$ to the Euler structure represented by v and extend equivariantly.)

Definition 2.4 [27] Let $(X; T)$ be a finite connected CW–complex with cells $\{\sigma_i\}$. (X denotes the underlying topological space; T denotes the cell structure.) A *combinatorial Euler structure* on $(X; T)$ is a choice of a lift of each cell to the universal abelian cover $\tilde{X}$, where two such sets of lifts $\{\tilde{\sigma}_i\}$ and $\{h_i\tilde{\sigma}_i\}$, with $h_i \in H_1(X) = \mathrm{Aut}(\tilde{X})$, are considered equivalent if $\sum_i (-1)^{\dim(\sigma_i)} h_i = 0$.

We let $\mathrm{Eul}(X; T)$ denote the space of combinatorial Euler structures of the CW–complex $(X; T)$. This is clearly an affine space over $H_1(X)$.

Note that if T' is a refinement of the cell-structure T with cells $\{\sigma'_j\}$, then there is a canonical isomorphism $\mathrm{Eul}(X; T) \to \mathrm{Eul}(X; T')$ sending $\{\tilde{\sigma}_i\}$ to $\{\tilde{\sigma}'_j\}$, where $\tilde{\sigma}'_j \subset \tilde{\sigma}_i$ if $\sigma'_j \subset \sigma_i$.

Lemma 2.5 [27] *If X is a closed smooth manifold with a smooth triangulation T, then there is a natural isomorphism between the spaces of smooth and combinatorial Euler structures:*

$$\mathrm{Eul}(X) \simeq \mathrm{Eul}(X; T).$$

The idea is that there is a natural vector field on each simplex with a zero at the center of each face and which points into the simplex near the boundary. These piece together to give a continuous vector field on X. We can perturb this to a smooth vector field v_T with a nondegenerate zero of sign $(-1)^i$ in the center of each i{simplex. Then a smooth Euler structure ξ can be represented by a chain γ consisting of paths connecting the zeroes in pairs, with $[\gamma] = i_{v_T}^{-1}(\xi) \in H_1(X; v_T)$. We can lift the chain γ to $\tilde{X}$, and the induced lifts of its endpoints determine a combinatorial Euler structure.

2.3 Reidemeister torsion

We now review the definition of Reidemeister torsion of certain chain complexes. We then use this algebra to define Reidemeister torsion for the two geometric complexes we are interested in.

2.3.1 Algebra

Let (C_*, ∂) be a finite complex of finite dimensional vector spaces over a field F. The standard short exact sequences $0 \to Z_i \to C_i \to B_{i-1} \to 0$ and $0 \to B_i \to Z_i \to H_i \to 0$ induce canonical isomorphisms $\det(C_i) = \det(Z_i) \otimes \det(B_{i-1})$ and $\det(Z_i) = \det(B_i) \otimes \det(H_i)$, where 'det' denotes top exterior power. Combining these isomorphisms gives an isomorphism

$$\Phi : \bigotimes_i \det(C_i)^{(-1)^i} \to \bigotimes_i \det(H_i)^{(-1)^i}. \tag{5}$$

Let e be an ordered basis for C_*, ie, an ordered basis e_i for each C_i. Let h be an ordered basis for H_*. Let $[e] \in \bigotimes_i \det(C_i)^{(-1)^i}$ and $[h] \in \bigotimes_i \det(H_i)^{(-1)^i}$ denote the resulting volume forms.

Definition 2.6 We define the *Reidemeister torsion*

$$\hat{\tau}(C_*; e; h) := \Phi([e])/[h] \in F^*.$$

We also define

$$\tau(C_*; e) := \begin{cases} \hat{\tau}(C_*; e; 1) & \text{if } H_* = 0, \\ 0 & \text{otherwise.} \end{cases}$$

Usually we will be interested in τ rather than $\hat{\tau}$. In practice, we can compute the torsion τ in terms of an alternating product of determinants as follows.

Lemma 2.7 *If $H = 0$, we can find a decomposition $C = A \oplus B$ such that (i) A_i and B_i are spanned by subbases of the basis e_i, and (ii) the map*

$$\pi_{B_{i-1}} \, \partial j_{A_i} : A_i \to B_{i-1}$$

(which we abbreviate by $\partial: A_i \to B_{i-1}$) is an isomorphism. Then

$$\tau(C; e) := \prod_i \det(\partial: A_i \to B_{i-1})^{(-1)^i}.$$

Here the determinants are computed using the subbases of e.

We now extend the definition of torsion to complexes over certain rings which might not be fields.

Definition 2.8 [28] Let R be a ring, and assume that its total quotient ring (denoted by $Q(R)$) is a finite sum of fields, $Q(R) = \bigoplus_j F_j$. Let $(C; \partial)$ be a finite complex of finitely generated free R–modules with an ordered basis e. We define

$$\tau(C; e) := \prod_j \tau(C \otimes_R F_j; e \otimes 1) \in \bigoplus_j F_j = Q(R).$$

In this case $H(C)$ might not be free, in which case it does not have a basis in the usual sense. However in this paper we call a set $h := \{h_j\}$ a "basis" for $H(C)$ when h_j is a basis for $H(C \otimes_R F_j)$ for each j. Given $h = \{h_j\}$, we define

$$\hat{\tau}(C; e; h) := \prod_j \hat{\tau}(C \otimes_R F_j; e \otimes 1; h_j) \in Q(R).$$

Example 2.9 If $0 \to C_2 \xrightarrow{\partial} C_1 \to 0$ is a 2–term complex with $C_1 = C_2$, and if e is a basis which is identical on C_1 and C_2, then

$$\tau(C; e) = \det(\partial).$$

We are interested in the rings $\mathbb{Z}[H_1]$ and Λ. Their quotients are finite sums of fields (see eg [28]), and these decompositions are compatible with the inclusion $\mathbb{Z}[H_1] \to \Lambda$.

In section 3.2, we will need the following product formula for torsion. Let R be a ring such that $Q(R)$ is a finite sum of fields F_j. Let $0 \to C \to C' \to C'' \to 0$ be a short exact sequence of finite complexes of finitely generated free R–modules. Let $e; e'; e''$ be bases for $C; C'; C''$ compatible with the exact sequence. Let $h; h'; h''$ be bases for the homology as in Definition 2.8. Let L denote the long exact sequence in homology, regarded as an acyclic chain complex, and let b denote the basis for L obtained by combining $h; h'; h''$.

Lemma 2.10 *We have the following product formula for torsion:*

$$\wedge(C'; e'; h') = \wedge(C; e; h)\wedge(C''; e''; h'') \quad (\in L \; / b):$$

Proof This follows from [16]. □

2.3.2 Geometry

We now de ne the Turaev torsion (3). In the notation of De nition 2.4, let $(X; T)$ be a nite connected CW{complex with universal abelian cover $\bar{X}$. Lif-ing the cells gives a chain complex $C(X; T)$ over $\mathbb{Z}[H_1(X)]$. A combinatorial Euler structure determines a set of lifts of each cell to $\bar{X}$, up to equiva-lence. Choose one set of lifts; this gives a basis for $C(X; T)$. A homology orientation o determines an orientation of this basis, via the isomorphism (5) applied to $C(X; T)$. Let $e(\; ; o)$ denote the resulting ordered basis. We de-ne the *combinatorial Turaev torsion* $(X; T; o)$ to be the H_1{equivariant map $\mathrm{Eul}(X; T) \;!\; Q(\mathbb{Z}[H_1])$ given by

$$(X; T; o)(\;) := (C(X; T); e(\; ; o)) \in Q(\mathbb{Z}[H_1]):$$

Note that the right hand side of this equation does not depend on the choice of a set of lifts. Furthermore, $(X; T; o) = (X; T; o)$ under the canonical isomorphism $\mathrm{Eul}(X; T) \;!\; \mathrm{Eul}(X; T)$, if T is a re nement of T.

De nition 2.11 Let X be a closed connected smooth manifold with $(X) = 0$, with a smooth Euler structure $\in \mathrm{Eul}(X)$ and a homology orientation o. Choose a smooth triangulation T of X. Let $_T \in \mathrm{Eul}(X; T)$ denote the combinatorial Euler structure equivalent to via Lemma 2.5. We de ne the *Turaev torsion*

$$(X; o)(\;) := (X; T; o)(\; _T):$$

The results of [27] show that the Turaev torsion does not depend on the choice of smooth triangulation T.

We now de ne the Morse theoretic torsion (4). A smooth Euler structure can be represented by a chain connecting the critical points of f in pairs, with $[\;] = i_{r f}^{-1}(\;) \in H_1(X; r f)$. We can lift to $\bar{X}$, and the induced lifts of the endpoints determine a basis $e(\;)$ for CN.

De nition 2.12 We de ne the *Morse theoretic torsion* $(CN): \mathrm{Eul}(X) \;!\; Q(\;) = 1$ by

$$(CN)(\;) := (CN; e(\;)):$$

The map (CN) is H_1–equivariant, and again does not depend on the choice of lifting. There is a sign ambiguity because the basis $e()$ is unordered. In the special case when f has no critical points, we define (CN) to be the H_1 equivariant map such that $(CN)() = 1$ for the smooth Euler structure represented by ∇f.

In the future, we call two bases for $C(X; T)$ or CN equivalent if they correspond to the same Euler structure .

2.4 The real-valued case

Before proceeding more deeply into circle-valued Morse theory, it will be useful to prove the main theorem for real-valued Morse functions.

Lemma 2.13 *Theorem 1.7 holds when $f: X \to S^1$ lifts to a real-valued Morse function $X \to \mathbb{R}$.*

Proof In this case $= 1$, so we just need to check that the Morse theoretic and topological torsions agree. This is essentially classical (cf [16]), except for the identification of the bases determined by an Euler structure.

If is an Euler structure, then the bifurcation analysis in [11] shows that $(CN)()$ is independent of the real-valued Morse function and the metric. It is not hard to check that the Euler structures work out at each stage. In [11] it is assumed that the metric has a standard form near the critical points, but this can be arranged by a perturbation which does not affect the Novikov complex.

Now let T be a smooth triangulation of X. We can apparently perturb the vector field V_T of section 2.2 so that it is the gradient of a Morse function $F: X \to \mathbb{R}$ with respect to some metric. In this case, the Novikov complex $(CN; \partial^F)$ is identical to the chain complex $(C(X; T); \partial)$. Moreover the bases determined by agree. Thus the Morse-theoretic and topological torsion are equal. □

3 Proof of the main theorem

We will now prove the main theorem as follows. In section 3.1 we prepare for the computation of torsion by constructing a cell complex X^θ which "approximates" X and is adapted to the vector field ∇f. In section 3.2 we prove a technical

lemma (Lemma 3.6) asserting that X and X^θ have the same Reidemeister torsion. The heart of the proof is in section 3.3 and section 3.4, where we determine the torsion of X^θ by a short computation, and then interpret the answer geometrically to recover the invariant I.

3.1   The cell complex X^θ

Assume $0 \in S^1 = \mathbb{R}/\mathbb{Z}$ is a regular value of f (by composing f with a rotation if necessary). Let $\Sigma := f^{-1}(0)$. Let Y be the compact manifold with boundary obtained by cutting X along Σ. We can write $\partial Y = \Sigma_1 \sqcup \Sigma_0$, where Σ_i is canonically isomorphic to Σ, and $-\nabla f$ points inward along Σ_1.

We give Y a cell decomposition as follows. Let T_1 be a smooth triangulation of Σ_1 such that each simplex is transverse to the ascending manifolds of the critical points in Y. If $p \in Y$ is a critical point, let $D_0(p)$ denote the descending manifold of p in Y. If $\sigma \in T_1$ is a simplex, let $F(\sigma)$ denote the set of all $y \in Y$ such that upward gradient flow starting at y hits σ. Choose a cell decomposition T_0 of Σ_0, such that the intersections with Σ_0 of $D_0(p)$ and $F(\sigma)$ are subcomplexes, for each critical point p and each simplex $\sigma \in T_1$.

Lemma 3.1 *The cells in T_1 and T_0, together with all the cells $D_0(p)$ and $F(\sigma)$, give a legitimate cell decomposition, T_Y^θ, of Y.*

Proof Recall that $D_0(p)$ and $F(\sigma)$ have natural compactifications using broken flow lines (cf [7]). It may be shown by "induction on height" that these compactifications are homeomorphic to closed balls. There are moreover natural continuous maps of the compactifications to Y which send the interiors of the balls homeomorphically to $D_0(p)$ and $F(\sigma)$. The transversality condition on T_1 and Assumption 1.1(b) ensure that the boundary of a cell consists of lower dimensional cells in T_Y^θ. $\square$

We would like to glue the boundary components of Y back together to obtain a nice cell decomposition of X, but usually T_0 will not agree with T_1. To correct for this, let $\phi : (\Sigma_0; T_0) \to (\Sigma_1; T_1)$ be a cellular approximation to the canonical identification $\Sigma_0 \to \Sigma_1$. Consider the mapping cylinder of ϕ:

$$M_\phi = \frac{(\Sigma_0 \times [0; 1]) \sqcup \Sigma_1}{(x; 1) \sim \phi(x)}.$$

This has a cell decomposition consisting of T_0 and T_1, together with the cells $\sigma \times (0; 1)$ for each $\sigma \in T_0$. There is a canonical inclusion $\Sigma_0 \to M_\phi$ sending $x \mapsto (x; 0)$, and there is also a canonical inclusion $\Sigma_1 \to M_\phi$.

Definition 3.2 Let X^θ be the space obtained by gluing Y and M along $\partial_0 t_1$.

The space X^θ inherits a cell decomposition, but for our computations we prefer a simpler cell decomposition, obtained by fusing some cells together as follows. If σ is a cell in Y of the form $D_0(p)$ or $F(\sigma)$, we define a corresponding cell in X^θ by

$$\hat{\sigma} := \sigma \cup ((\partial\sigma \setminus \partial_0) \times [0,1)).$$

Here $(\partial\sigma \setminus \partial_0) \times [0,1)$ indicates a subset of M.

Definition 3.3 Let T^θ be the cell decomposition of X^θ consisting of cells of the following types:

(a) $\widehat{D_0(p)}$ for $p \in Y$ a critical point;

(b) simplices in T_1;

(c) $\widehat{F(\sigma)}$ for $\sigma \in T_1$.

3.2 X and X^θ have the same Reidemeister torsion

We now show that X and X^θ have the same Reidemeister torsion, if the Euler structures are compatible in an appropriate sense.

We begin by noting that $H_*(X^\theta) = H_*(X)$, and $H_*(\tilde{X}^\theta) = H_*(\tilde{X})$ as $\mathbb{Z}[H_1]$-modules, as one can see from the exact sequences (8), (9) below. Note that the universal abelian cover $\tilde{X}^\theta$ of X^θ is obtained from $\tilde{X}$ by modifying a neighborhood of the inverse image of γ.

Notation 3.4 (1) If Z is a subset of X or X^θ, then $\bar{Z}$ will denote the inverse image of Z in $\tilde{X}$ or $\tilde{X}^\theta$. So $\bar{Z}$ is usually not the universal abelian cover of Z.

(2) We omit the cell structures from the notation when they are clear from context.

A smooth Euler structure ξ on X corresponds to an equivalence class of lifts of the critical points of f to $\tilde{X}$, as in section 2.3.2. A combinatorial Euler structure ξ^θ on X^θ consists of an equivalence class of lifts of the cells T^θ to $\tilde{X}^\theta$.

Definition 3.5 We say that ξ and ξ^θ are *compatible* if, within these equivalence classes, the lifts can be chosen so that:

(a) The lift of each critical point p in   is contained in the lift of the cell $\widehat{D_0(p)}$ in $^\emptyset$.

(b) For each simplex $\in T_1$, the lift of   in $^\emptyset$ agrees with the \top" of the lift of $\widehat{F(\ )}$ in $^\emptyset$.

The compatibility conditions in De nition 3.5 induce an isomorphism from $\mathrm{Eul}(X)$ to $\mathrm{Eul}(X^\emptyset; T^\emptyset)$ as a ne spaces over H_1.

Recall that $(X) :=$ $(X; o)$; similarly write $(X^\emptyset; T^\emptyset) :=$ $(X^\emptyset; T^\emptyset; o)$.

Lemma 3.6 *If the Euler structures* $\in \mathrm{Eul}(X)$ *and* $^\emptyset \in \mathrm{Eul}(X^\emptyset; T^\emptyset)$ *are compatible as above, then*

$$(X)(\ ) =\quad (X^\emptyset; T^\emptyset)(\ ^\emptyset):$$

Proof The strategy is to compute the torsion of X and $X^\emptyset$ by cutting them into pieces and using the product formula (Lemma 2.10) applied to various exact sequences, and see that we obtain the same answer. We proceed in three steps.

Step 1 Consider the cell decomposition on ~ $\times [0; 1]$ consisting of cells ~ $\times f0g$, ~ $\times (0; 1)$, and ~ $\times f1g$, where ~ is a lift of a simplex $\in T_1$. Also recall that M has a natural cell decomposition. We claim that with respect to these cell structures,

$$\wedge(C \ (\sim \times [0; 1]); e\ ; h) =\quad \wedge(C \ (M\ ); e^\emptyset\ ; h^\emptyset); \qquad (6)$$

provided that the bases $e\ ; h; e^\emptyset\ ; h^\emptyset$ satisfy the following conditions:

(a) The bases $h; h^\emptyset$ for homology agree under the isomorphism induced by the canonical map $\times [0; 1] \to M$.

(b) The bases $e\ ; e^\emptyset$ are given by lifts of cells such that:

 (i) The lifts of the cells in $\times f1g$ $\times [0; 1]$ and $_1$ M agree.

 (ii) The lift of each cell   in $\times f0g$ $\times [0; 1]$ or in $_0$ $f0g$ M is adjacent to the lift of the cell $\times (0; 1)$ in $\times [0; 1]$ or M respectively.

To prove (6), we compute both sides by applying the product formula for torsion to the relative exact sequences

$$0 \to\ C \ (\sim \times f1g) \to\ C \ (\sim \times [0; 1]) \to\ C \ (\sim \times [0; 1]; \sim \times f1g) \to\ 0;$$

$$0 \to\ C \ (\sim_1) \to\ C \ (M\ ) \to\ C \ (M\ ; \sim_1) \to\ 0:$$

The answers agree, because condition (a) implies that the (L) factors agree, condition (b(i)) implies that the $\wedge(C(\tilde{}))$ factors agree, and condition (b(ii)) implies that

$$\wedge(C(\tilde{}\quad[0;1];\tilde{}\quad f1g);e\ ;1) = \wedge(C(M\ ;\tilde{}_1);e^{\theta}\ ;1) = 1:$$

Step 2 Let T_Y be a smooth triangulation on Y whose restriction to each component of $@Y = \ _0\ t\ \ _1$ agrees with T_1. The smooth Euler structure on X determines an equivalence class of bases, e_Y, for $C(Y;\tilde{}_0;T_Y)$, because T_Y glues to a smooth triangulation of X.

Let T_Y^{θ} denote the cell decomposition of Y given by Lemma 3.1. The combinatorial Euler structure $\ ^{\theta}$ on X^{θ} determines an equivalence class of bases e_Y^{θ} for $C(Y;\tilde{}_0;T_Y^{\theta})$, because the cells of T_Y^{θ} in $Y\ n\ \ _0$ are in one to one correspondence with the cells of X^{θ}.

We claim that

$$\wedge(C(Y;\tilde{}_0;T_Y^{\theta});e_Y^{\theta};h^{\theta}) = \wedge(C(Y;\tilde{}_0;T_Y);e_Y;h) \tag{7}$$

provided that the bases h^{θ} and h on homology agree.

To prove (7), note that the pullback of the Morse function f to Y lifts to a real-valued function $\hat{f}:Y\ !\ \mathbb{R}$. Let $CM(\hat{f})$ denote the Morse complex of $\hat{f}$ on the covering Y. A direct computation, using the compatibility of $\ $ and $\ ^{\theta}$, shows that

$$\wedge(C(Y;\tilde{}_0;T_Y^{\theta});e_Y^{\theta};h^{\theta}) = \wedge(CM(\hat{f});e^{\theta\theta};h^{\theta\theta}):$$

(For similar calculations see section 3.3 and section 3.4; the result here corresponds essentially to setting $t = 0$ in (11) and Lemma 3.7.) Here the basis $e^{\theta\theta}$ for $CM(\hat{f})$ is determined by the lifts of the critical points determined by as before, and we assume that the bases $h^{\theta};h^{\theta\theta}$ on homology agree under the standard isomorphism $H(Y;\tilde{}_0)\ '\ H(CM(\hat{f}))$.

We also have

$$\wedge(CM(\hat{f});e^{\theta\theta};h^{\theta\theta}) = \wedge(C(Y;\tilde{}_0;T_Y);e_Y;h):$$

The idea of the proof is to vary $\hat{f}$ in the space of Morse functions on Y such that (i) the gradient points outward along $\ _0$ and does not point outward along $\ _1$, and (ii) wherever the gradient is tangent to $\ _1$, the inward covariant derivative of the gradient points inward. As in section 2.4, one can show that the resulting torsion is independent of the Morse function. Deforming $\hat{f}$ to a Morse function F_Y adapted to the triangulation T_Y, such that $CM(F_Y) = C(Y;\tilde{}_0;T_Y)$, we have $\wedge(CM(\hat{f});e^{\theta\theta};h^{\theta\theta}) = \wedge(CM(F_Y);i_{fF}(e^{\theta\theta});h^{\theta\theta})$, where $i_{fF}(e^{\theta\theta})$ is the

equivalence class of lifts (which correspond to bases of CM) induced from $e^{\prime\prime\prime}$ via the homotopy from $\hat{F}$ to F_Y. But $i_{FF}(e^{\prime\prime\prime}) = e_Y$ because the homotopy from $r\hat{F}$ to rF_Y extends to a homotopy of vector fields on $X = Y \amalg (\quad I)$, which is homotopic to a homotopy from rf to the standard vector field associated to the triangulation of X (cf end of section 2.2).

The above two equations prove (7).

Step 3 We now use (6) and (7) to compute the torsion of X and $X^{\prime}$.

We can regard X as the union of Y and $[0;1]$ along $_0 t_1$. Let $\overline{T}$ denote the cell decomposition of X obtained by gluing the triangulation T_Y of Y to the product cell structure on $[0;1]$ obtained from T_1. We then have a short exact sequence

$$0 \to C \quad \tilde{}_0 t \tilde{}_1 \to C (\tilde{} \quad [0;1]) \quad C (Y;T_Y) \to C (X;\overline{T}) \to 0; \quad (8)$$

Let $\overline{T}^{\prime}$ denote the \unfused" cell decomposition of $X^{\prime}$ from section 3.1. We then have a short exact sequence

$$0 \to C \quad \tilde{}_0 t \tilde{}_1 \to C (M) \quad C (Y;T_Y^{\prime}) \to C (X^{\prime};\overline{T}^{\prime}) \to 0; \quad (9)$$

We can choose representatives $e_Y ; e_Y^{\prime}$ such that they agree on $f1g$ and $_1$ with $e ; e^{\prime}$ respectively. Let $e(\ )$ denote the basis for $C (X;\overline{T})$ obtained by combining the bases $e ; e_Y$ of Step 1 and Step 2 respectively. Similarly let $e^{\prime}(\ ^{\prime})$ denote the basis for $C (X^{\prime};\overline{T}^{\prime})$ obtained by combining the bases $e^{\prime} ; e_Y^{\prime}$ of Step 1 and Step 2. Then $e(\ )$ is a representative of the combinatorial Euler structure on $(X;T)$ corresponding to the smooth Euler structure , and $e^{\prime}(\ ^{\prime})$ is a representative of the image of $^{\prime}$ under the canonical isomorphism $\mathrm{Eul}(X^{\prime};T^{\prime}) \to \mathrm{Eul}(X^{\prime};T^{\prime})$.

Applying the product formula to the above exact sequences, and using equations (6) and (7), we obtain

$$\wedge(C (X;\overline{T}); e(\ ); h) = \wedge(C (X^{\prime};\overline{T}^{\prime}); e^{\prime}(\ ^{\prime}); h^{\prime}); \quad (10)$$

Here we are assuming that the bases $h ; h^{\prime}$ for homology agree under the natural isomorphism $H (X) \simeq H (X^{\prime})$. Also, to apply (7) in the above computation, one relates Y to the pair $(Y ; _0)$ as in Step 1.

In particular, equation (10) implies that

$$(C (X;\overline{T}); e(\ )) = (C (X^{\prime};\overline{T}^{\prime}); e^{\prime}(\ ^{\prime}));$$

This implies the lemma because $(C (X;\overline{T}); e(\ )) = (X)(\ )$, since the insertion of $[0;1]$ changes nothing, and similarly $(C (X^{\prime};\overline{T}^{\prime}); e^{\prime}(\ ^{\prime})) = (X^{\prime};T^{\prime})(\ ^{\prime})$. □

3.3 Computing the torsion

We now compute the torsion of the approximating cell complex $(X^\theta; T^\theta)$, for a combinatorial Euler structure θ compatible with a smooth Euler structure on X as in the previous section.

Since Lemma 2.13 proves the theorem for real-valued Morse functions, we assume from now on that

$$\gamma \neq 0:$$

Without loss of generality, we may also assume that γ is indivisible in $H^1(X; \mathbb{Z})$. (If γ is divisible by k, we can lift f to a $k\{$fold cover of S^1 without changing the invariant I.) Let $V := \mathrm{Ker}(\gamma)$, and choose a splitting

$$H_1(X) = V \quad \mathbb{Z}:$$

Let t denote the generator of the $\mathbb{Z}$ component with $\gamma(t) = -1$. Then the Novikov ring Λ can be identified with the ring of formal Laurent series in t with coefficients in $\mathbb{Z}[V]$:

$$\Lambda = \mathbb{Z}[V]((t)):$$

Recall that $Q(\Lambda)$ is a finite sum of fields. To prove Theorem 1.7, it suffices to show that it holds after projecting to each such field. Let K be a field component of $Q(\Lambda)$. By the Novikov isomorphism (Theorem 2.1), the complexes $CN \otimes K$ and $C(\tilde{X}) \otimes K$ have isomorphic homology. So we will assume that these complexes are both acyclic, since otherwise they both have zero torsion τ, and there is nothing to prove. In all of the calculations below, we implicitly tensor everything with the field K.

We can decompose

$$C_i(X^\theta) = D_i \quad E_i \quad F_i$$

where the three summands are generated by the cells of types (a), (b), and (c) respectively from Definition 3.3. Let us choose a basis $e(\theta)$ for $C_i(X^\theta)$ as in Definition 3.5. We can identify

$$F_i \simeq E_{i-1}:$$

The matrix for the boundary operator on $C_i(X^\theta)$ can then be written as

$$\partial_i = \begin{array}{c} \\ D_{i-1} \\ E_{i-1} \\ F_{i-1} \end{array} \begin{pmatrix} D_i & E_i & F_i \\ \mathbf{N}_i & 0 & \mathbf{W}_i \\ -t\mathbf{M}_i & \partial_i & 1 - t_{i-1} \\ 0 & 0 & -\partial_{i-1} \end{pmatrix}: \tag{11}$$

We remark that ∂_i is the boundary operator on $C_*(\tilde{Y})$. Also Δ_{i-1} is a matrix with entries in $\mathbb{Z}[V]$, which can be interpreted as the return map of the gradient flow from $\tilde{Y}$ to $\tilde{Y}$, after perturbation by our cellular approximation ϕ. Likewise $\mathbf{M}_i$ sends $\widehat{D_0(p)}$, where $p \in X$ is a critical point, to a perturbation of the "descending slice" $\widehat{D_0(p)} \cap \tilde{Y}$.

Continuing the calculation, due to the acyclicity assumption we may choose decompositions $D_i = D_i^A \oplus D_i^B$ such that D_i^A and D_i^B are spanned by (cells corresponding to) critical points, and the differential ∂^f induces an isomorphism $D_i^A \to D_{i-1}^B$. In the notation below, we denote matrices with domain or range D_* by boldface letters, and we denote their restrictions to D_i^A and/or projections to D_{i-1}^B by plain letters.

We now apply Lemma 2.7 with $A_i = D_i^A \oplus F_i$ and $B_i = D_i^B \oplus E_i$. (We will explain in a moment why this choice of A_i and B_i is legitimate.) We obtain

$$\tau(C_*(X^0; e(\phi^0)) = \prod_{i=1}^{n} \det(\Delta_i)^{(-1)^{i+1}}$$

where

$$
\Delta_i = \begin{array}{c@{}c}
 & \begin{array}{cc} D_i^A & \quad F_i \end{array} \\
\begin{array}{c} D_{i-1}^B \\ E_{i-1} \end{array} & \left(\begin{array}{cc} N_i & W_i \\ -tM_i & 1 - t\Delta_{i-1} \end{array} \right) :
\end{array}
$$

We note that $1 - t\Delta_{i-1}$ is invertible because Δ_{i-1} has entries in $\mathbb{Z}[V]$. It follows that

$$\det(\Delta_i) = \det(1 - t\Delta_{i-1}) \det(K_i)$$

where

$$\mathbf{K}_i := \mathbf{N}_i + t\mathbf{W}_i(1 - t\Delta_{i-1})^{-1}\mathbf{M}_i : D_i \to D_{i-1}: \tag{12}$$

It will follow from Lemma 3.9(b) and the choice of D_i^A, D_i^B that K_i is nonsingular, provided that the triangulation T_1 is sufficiently fine and the cellular approximation ϕ is sufficiently close to the identity. In particular, the matrices Δ_i are then nonsingular, so that Lemma 2.7 legitimately applies to the A_i and B_i chosen above.

In conclusion, the above calculations imply the following lemma.

Lemma 3.7 *If T_1 is sufficiently fine and ϕ is sufficiently close to the identity, then*

$$\tau(C_*(X^0))(\phi^0) = \prod_{i=1}^{n} \left[\det(1 - t\Delta_{i-1}) \det(K_i) \right]^{(-1)^{i+1}}:$$

3.4   Geometric interpretation

We will now interpret the factors on the right side of Lemma 3.7 in terms of Morse theory.

Notation 3.8 Suppose x, y are elements of $\quad = \mathbb{Z}[V]((t))$, or matrices with entries in $\quad$, which might depend on the choice of triangulation T_1 and cellular approximation $\quad$. We write

$$x \quad y$$

if $x - y = O(t^k)$, where k can be made arbitrarily large by choosing T_1 su -ciently ne and $\quad$ su ciently close to the identity.

Lemma 3.9   (a) $\quad \bigcirc_{i=0}^{n-1} \det(1 - t_{\ i})^{(-1)^i}$.

(b) *Under the natural identi cation $D \ ' \ CN$, we have*

$$\mathbf{K}_i \quad @_i^f :$$

Proof (a) Let $\hat{f} \colon X \,!\; \mathbb{R}$ be a lift of f, and let $\tilde{\ } := \hat{f}^{-1}(0)$. The downward gradient flow of $\hat{f}$ induces partially de ned return maps

$$'^k \colon \tilde{\ } \,!\; t^k \tilde{\ } :$$

The de nition (1) of $\quad$ is equivalent to

$$= \exp^{@} \bigcirc \overset{\times}{\underset{k>0, \ g2V}{}} \mathrm{Fix}('^k \quad t^{-k} g^{-1}) \frac{g t^k}{k} \overset{1}{A} \ 2 \ \mathbb{Z}[V]((t)) = \quad : \tag{13}$$

Here $\mathrm{Fix}(s)$ counts xed points of the equivariant map s modulo covering transformations, with their Lefschetz signs.

Suppose to begin that $\quad = \mathrm{id}$. By the machinery used to prove the Lefschetz xed point theorem in [1], for each k we have

$$\overset{\times}{\underset{g2V}{}} \mathrm{Fix}('^k \quad t^{-k} g^{-1}) \ g = \overset{n-1}{\underset{i=0}{\times}} (-1)^i \mathrm{Tr}(\ _i^k) \ 2 \ \mathbb{Z}[V] : \tag{14}$$

In this case we have

$$= \overset{n-1}{\underset{i=0}{\prod}} \det(1 - t_{\ i})^{(-1)^i} : \tag{15}$$

To see this, it is enough to check that the logarithmic derivatives of both sides are equal, which follows from equations (13) and (14).

In general, let H: $[0;1]$ $!$ be the homotopy from id to . In [7] we de ned a natural compacti cation of the graph of $'$. Using this one can de ne a compacti ed graph $\overline{}_t^i$ of $(H(;t) ')^i)$ in a similar manner. Now there exists a positive integer N such that if the cells in T_1 are all contained in balls of radius , then the homotopy H can be chosen so that $\text{dist}(H(t;x);x) < N$ for all $t \in [0;1]$ and $x \in$. (Cf the construction of H in [23]; by carefully controlling each intermediate step in the homotopy, the above claim may be achieved.) Also, the set of xed points of $'^i$ lies in the interior of ^{i} under the diagonal map $!$ by de nition of ^{i}, and is compact as a consequence of Assumption 1.1. It follows that for any positive integer k we can choose so that for all i k and all $t \in [0;1]$, the compacti ed graph $\overline{}_t^i$ does not cross the diagonal in . Then equation (14) will hold up to order k, and therefore so will equation (15).

(b) If p is a critical point of index i, then

$$@[D(p)] = [D(@^f p)] \tag{16}$$

where the brackets indicate the fundamental class of the compacti cation of the descending manifold [7]. Now suppose again that $= \text{id}$. Recall from equation (12) that the matrix $\mathbf{K}_i$ sends $\widehat{D_0(p)}$ to a linear combination of cells of the form $\widehat{D_0(q)}$, where q is a critical point of index $i - 1$. (We will henceforth omit the hats $\wedge$ on D_0 or F when $= \text{id}$, since in this case hatted and unhatted versions can be identi ed.) In fact,

$$\mathbf{K}_i(D_0(p)) = D_0(@^f(p)):$$

To see this, note that from the de nition of $\mathbf{M}_i$ in equation (11), we have

$$[D(p)] = D_0(p) + \sum_{k=0}^{\infty} t^{k+1} F(\; ^k \mathbf{M}_i(D_0(p))):$$

(Here the initial descending manifolds D_0 and initial downward flow F are de ned as in section 3.1, but using X and $\sim$ instead of X and .) Applying equation (11) to this gives

$$@[D(p)] = \mathbf{K}_i(D_0(p)) + \text{(terms without initial descending manifolds).} \tag{17}$$

Equations (16) and (17) imply that $@_i^f = \mathbf{K}_i$ when D (the domain/range of $\mathbf{K}$) is identi ed with CN.

The case $\neq \text{id}$ can be handled similarly to part (a). $\qquad\square$

We can now complete the proof of Theorem 1.7. Lemmas 3.9(b) and 2.7 imply that

$$\prod_{i=1}^{n} \det(K_i))^{(-1)^{i+1}} \qquad (CN)( ).$$

Together with Lemmas 3.6, 3.7, and 3.9(a), this implies that Theorem 1.7 holds up to order k for all k.   □

4 The 3{dimensional case and Seiberg{Witten theory

We now review from [7] the de nition of the Morse-theoretic invariant I_3, and the background for Conjecture 1.9 relating this invariant to Seiberg{Witten theory. We will then prove Theorem 1.12, relating this invariant to Turaev torsion.

4.1 Motivation from Seiberg{Witten theory

Let X be a closed connected oriented smooth 3{manifold with $b_1(X) > 0$. Let $\mathfrak{s}$ be a spin-c structure on X. This determines a $U(2)${bundle $S \to X$ with a Cli ord action of TX on S. A section of S and a connection A on $\det(S)$ satisfy the Seiberg{Witten equations with perturbation $!$ if, in the notation of [9],

$$\mathscr{D}_A \quad = 0;$$
$$(F_A) = i \ (\ ; \ ) + i \ (!):$$

The Seiberg{Witten invariant $SW(\mathfrak{s})$ counts solutions to these equations modulo gauge equivalence. (For more on 3{dimensional Seiberg{Witten invariants see eg [13, 14, 18].)

Let us choose the perturbation to be $! = r \ df$, where $f \colon X \to S^1$ is harmonic, denotes the Hodge star, and r is a real number. By perturbing the metric, we may arrange that f is a Morse function. Away from the critical points, the spinor bundle S splits into eigenspaces of Cli ord multiplication by df,

$$S = E \quad (E \quad K^{-1}); \tag{18}$$

where $K^{-1} := \mathrm{Ker}(df \colon TX \to \mathbb{R})$.

Taking $r \to \infty$, one expects that for a Seiberg–Witten solution the zero set of the E component of ϕ to become parallel to $r \nabla f$. (The energy of the Seiberg–Witten solution will be concentrated along this zero set. For detailed analysis see [24] and its sequels.) This suggests that $SW(\mathfrak{s})$ counts unions of closed orbits and flow lines of $r \nabla f$ starting and ending at critical points, whose total homology class is Poincaré dual to $c_1(E)$.

The above homological condition implies that in our union of closed orbits and flow lines there is precisely one flow line starting at each index 2 critical point and ending at each index 1 critical point. (See [7]. There are no index 0 or 3 critical points because f is harmonic, and there are equally many index 1 and index 2 points because $\chi(X) = 0$.) In other words, in the notation of section 2.2, our union of closed orbits and flow lines lives in $H_1(X; v)$, where $v = -r \nabla f$. As in Remark 1.10, the counting of closed orbits is related to Taubes' counting of pseudoholomorphic tori in symplectic 4–manifolds [25], which indicates that we should allow closed orbits to be multiply covered when they are elliptic, but not when they are hyperbolic.

4.2 The definition of I_3

We now want to define $I_3(\mathfrak{s})$ to be a signed count of such unions of closed orbits and flow lines. A convenient way to do so is to use generating functions as follows. Choose orderings of the index 1 and index 2 critical points. Let P^{ij} denote the set of flow lines from the ith index 2 point to the jth index 1 point. Define the path matrix P by

$$P^{ij} := \sum_{\gamma \in P^{ij}} \epsilon(\gamma)[\gamma].$$

Here $[\gamma] \in H_1(X; v^{-1}(0))$ is the homology class of γ (oriented downward), and $\epsilon(\gamma)$ is the sign of γ as in section 2.1. The entries of P live in the Novikov ring of the relative homology group $H_1(X; v^{-1}(0))$ with grading given by minus intersection number with α.

Note that $\det(P)$, regarded as a $\mathbb{Z}$–valued function on $H_1(X; v^{-1}(0))$, is supported on $H_1(X; v)$. Also, the subset of $\mathrm{Nov}(H_1(X; v^{-1}(0)))$ consisting of functions supported on $H_1(X; v)$ is a Λ–submodule. A generating function counting unions of closed orbits and flow lines of the type we want is now given by

$$I_3^v := \zeta \cdot \det(P) \in \mathrm{Nov}(H_1(X; v)).$$

In the above equation, '$\cdot$' denotes the Λ action. The closed orbits are counted correctly as a result of the product formula for the zeta function (2).

Let j_v: $\mathrm{Spin}^c(X) \to H_1(X; v)$ denote the map that sends a spin-c structure to the Poincaré–Lefschetz dual of $c_1(E)$, where E is the line bundle defined in (18). The map j_v is an H_1–equivariant isomorphism.

Definition 4.1 [7] Regarding I_3^v as a function $H_1(X; v) \to \mathbb{Z}$, we define

$$I_3 := I_3^v \circ j_v \colon \mathrm{Spin}^c(X) \to \mathbb{Z}.$$

This definition makes sense for any Morse function $f\colon X \to S^1$ with no index 0 or 3 critical points, even if f is not harmonic. The calculation below will show that I_3 does not depend on f, except that there is a global sign ambiguity in I_3 due to the orientation choices we made. (Also I_3 depends on the sign of $\xi \in H^1(X; \mathbb{Z})$ when $b_1(X) = 1$.)

4.3   Relation with Turaev torsion

To relate I_3 to torsion, we note that the isomorphism $i_v \circ j_v \colon \mathrm{Spin}^c(X) \to \mathrm{Eul}(X)$ does not depend on v. It follows that there is a canonical isomorphism $\iota\colon \mathrm{Spin}^c(X) \to \mathrm{Eul}(X)$. (This isomorphism was first defined by Turaev [27] in a different but equivalent way. The inverse map sends a smooth Euler structure represented by a nonsingular vector field u to the spin-c structure whose spin bundle is $\mathbb{C}u \oplus u^?$ with a standard Clifford action.) In summary, we have the following commutative triangle:

$$
\begin{array}{ccc}
H_1(X; v) & \xrightarrow{\ i_v\ } & \mathrm{Eul}(X) \\
\quad{}_{j_v}\searrow & & \nearrow{}_{\iota} \\
& \mathrm{Spin}^c(X) &
\end{array}
$$

Proof of Theorem 1.12   It is enough to show that

$$I_3^v \circ i_v^{-1} = \pm T(X; o)\colon \mathrm{Eul}(X) \to \mathbb{Z}.$$

By Theorem 1.7 and the definition of T, this is equivalent to asserting that for some orientation choice, we have

$$\det(P)(i_v^{-1}(\xi)) = \pm(CN)(\xi)(0)$$

for all Euler structures ξ. If ξ_0 is a reference Euler structure and $\gamma := i_v^{-1}(\xi_0) \in H_1(X; v)$, then this equation is equivalent to

$$\det(P)(\gamma + \cdot) = \pm(CN)(\xi_0)(\cdot)\colon H_1 \to \mathbb{Z}.$$

This last equation follows from the definition of (CN) and Example 2.9. □
